A chemical map of NaSICON electrode materials for sodium-ion batteries†

Baltej Singh,‡a Ziliang Wang,‡a Sunkyu Park,bcd Gopalakrishnan Sai Gautam, id e Jean-Noël Chotard, bdf Laurence Croguennec, i,jid Dany Carlier, cdf Anthony K. Cheetham, i,ag Christian Masquelier ib df and Pieremanuele Canepa i,b,e

Na-ion batteries are promising devices for smart grids and electric vehicles due to the cost effectiveness arising from the overall abundance of sodium (Na) and its even geographical distribution. Among other factors, the energy density of Na-ion batteries is limited by the cathode electrode chemistry. NaSICON-based electrode materials are known for their wide range of electrochemical potentials, high ionic conductivity, and most importantly their structural and thermal stabilities. Using first-principles calculations, we chart the chemical space of 3d transition metal-based NaSICON phosphates with the formula $\text{Na}_x\text{M}^+\text{M}^{Ⅶ}_2(\text{PO}_4)_3$ (with $\text{M}^+$ and $\text{M}^{Ⅶ}$ = Ti, V, Cr, Mn, Fe, Co and Ni) to analyze their thermodynamic stabilities and the intercalation voltages for Na$^+$ ions. Specifically, we compute the Na insertion voltages and related properties of 28 distinct NaSICON compositions. We investigate the thermodynamic stability of Na-intercalation in previously unreported Na$_x$Mn$_2$(PO$_4$)$_3$ and Na$_x$VCo(PO$_4$)$_3$. The calculated quaternary phase diagrams of the Na–P–O–Co and Na–P–O–Ni chemical systems explain the origin of the suspected instability of Ni and Co-based NaSICON compositions. From our analysis, we are also able to rationalize anomalies in previously reported experimental data in this diverse and important chemical space.

**1. Introduction**

Developing new battery systems capable of storing increasing quantities of energy poses extraordinary scientific and economic challenges. Lithium (Li)-ion batteries power the world’s portable devices, such as mobile phones, cameras, laptops, etc., but the supply chains of Li and the required transition metals may soon be at risk due to geopolitical considerations.1,2 Sodium (Na) appears to be a viable alternative to Li for battery applications due to its earth abundance, as well as the possibility of harvesting it directly from sea water. With Na being ~50 times more affordable compared to Li, Na-ion batteries (NIBs) are being explored by researchers worldwide, including a number of commercialization attempts.1,4 In addition, inexpensive stainless-steel current collectors are typically used in NIBs instead of the expensive copper ones found in Li-ion cells.

Cathode materials factor prominently in the overall energy density stored by NIBs, and the optimization of electrode chemistries to provide high intercalation voltages and gravimetric/volumetric capacities remains a crucial aspect in the design of competitive NIBs. In theory, transition metal layered oxide-based cathode materials for NIBs would offer the largest theoretical energy densities.3,7–9,40 However, the dominant two dimensional character of their structures strongly affects the longevity of the cathode material, with the electrochemical cell exhibiting a shorter-than-desired cycle life.6,7,28–31 Promising alternatives to layered oxides are polyanion-based cathode materials.33 Polyanion electrode materials leverage a combination of multivalent cations (e.g., $\text{P}^{5+}$, $\text{Si}^{4+}$ and $\text{Sn}^{4+}$) and anions (mostly $\text{O}^{2-}$) arranging into phosphate, silicate and sulfate ($\text{PO}_4^{3-}$, $\text{SiO}_4^{4-}$ and $\text{SO}_4^{2-}$), which are thermodynamically stable by virtue of the strong binding energy of their polyanionic covalent bonds.17–19
An important class of phosphate electrodes discovered by Hong and Goodenough is the Natrium Super Ionic CONductors (NaSICONs), which can be written as Na$_x$M$_2$$(XO_4)_3$, where M and M' are metals and X = Si, P, or S. NaSICON electrode materials and electrolytes typically display a Na$^+$ mobility. The NaSICON framework is important for the development of new NIB materials, since its structural tunability enables the exploration of a vast chemical space, which greatly diversifies the potential, electrochemical properties and related structural features. In theory, a charged state of the battery the anode is Na$_4$V$^IV$V$^III$(PO$_4$)$_3$ and the di charged state of the battery the anode is Na$_4$V$^IV$V$^III$(PO$_4$)$_3$ as the pristine material and Na$_4$V$^IV$V$^III$(PO$_4$)$_3$ as the pristine material to Na$_4$V$^IV$V$^III$(PO$_4$)$_3$, is possible but not practical due to the 1.8 V difference between the two processes (V$^IV$/V$^III$ and V$^III$/V$^IV$) and the difficult synthesis of Na$_4$V$_4$(PO$_4$)$_3$. Ueubo et al. demonstrated the extraction of Na$^+$ ions with partial reversibility.

Symmetric Na electrochemical cells entirely made of NaSICON framework adopt NVP as both the electrodes; in the charged state of the battery the anode is Na$_4$V$^IV$V$^III$(PO$_4$)$_3$ and the cathode is Na$_4$V$^IV$V$^III$(PO$_4$)$_3$, with Na$_2$Zr$_2$Si$_2$PO$_12$ as the electrolyte. This could deliver an average voltage of 1.8 V. NVP suffers from poor intrinsic electronic conductivity due to the isolated VO$_6$ octahedra, which are never face-, edge- or corner-sharing with each other, in contrast to their arrangement in layered-oxide cathodes where edge-sharing exists between MO$_6$ moieties.

The Ti analogue of NVP is the Ti$^IV$-containing Na$_4$Ti$_{2}$Ti$_{IV}$(PO$_4$)$_3$ composition, which is stable in air and can reversibly exchange two electrons by benefitting from the Ti$^IV$/Ti$^{III}$ redox couple, but at a lower voltage of 2.1 V vs. Na/Na$^+$. This is compared to that of 3.4 V for V$^IV$/V$^III$ redox in NVP. Na$_4$Ti$_{2}$Ti$_{IV}$(PO$_4$)$_3$ is also commonly used as a negative electrode material. The NaSICON Na$_4$Fe$^{III}$Fe$^{II}$(PO$_4$)$_3$ exhibits a voltage-composition plateau at 2.5 V vs. Na/Na$^+$ with a discharge capacity of 61 mA h g$^{-1}$ and is associated with the redox couple Fe$^{III}$/Fe$^{II}$. The Fe$^{IV}$/Fe$^{III}$ redox couple was claimed to be observed in Na$_4$Fe$^{III}$Fe$^{II}$(PO$_4$)$_3$ at 3.4 V vs. Na/Na$^+$, with a limited specific discharge capacity of 22 mA h g$^{-1}$. Nevertheless, the formation of tetravalent iron ions has not yet been reproduced.

Yamada et al. reported a voltage of 4.5 V vs. Na/Na$^+$ (enabled by the reversible Cr$^{IV}$/Cr$^{III}$ redox couple) when Na$^+$ is extracted from Na$_2$Cr$^{III}$Cr$^{IV}$(PO$_4$)$_3$, which corresponds to the highest voltage ever reported among NaSICON materials with a single TM species. Importantly, the Mn, Co and Ni, Na$_x$M$_2$(PO$_4$)$_3$ NaSICON analogues have not yet been reported.

The high voltage delivered by the Cr$^{IV}$/Cr$^{III}$ redox couple offers scope for exploring new high-voltage/capacity materials using more than one TM, e.g., Na$_x$Cr$^{III}$Mn$^{III}$(PO$_4$)$_3$. Other NaSICON materials, such as Na$_x$M$^{IV}$M$^V$(PO$_4$)$_3$ and Na$_2$Ti$^{IV}$(PO$_4$)$_3$, have been studied to enable high reversible capacity and longevity as anode and cathode electrodes.

In general, to access three electrons (i.e., 3 Na$^+$ ions per 2 TMs per formula unit) in any mixed TM NaSICON, two criteria must be met: (i) the TM must be in the +2 and +3 oxidation states in the fully discharged state (i.e., 4 Na$^+$ ions) and (ii) at least one of the TMs must accommodate multiple redox active oxidation states. Compounds that meet these criteria are mainly either Mn or V-based NaSICONs, e.g., Na$_2$Ti$^{IV}$V$^{III}$(PO$_4$)$_3$, Na$_x$Ti$^{IV}$Mn$^{II}$(PO$_4$)$_3$, Na$_x$Mn$^{IV}$V$^{III}$(PO$_4$)$_3$, and Na$_x$Cr$^{II}$Mn$^{III}$(PO$_4$)$_3$, which undergo reversible electrochemical reactions up to three electrons with average voltages of 2.4, 3.2, 3.4, and 4.1 V vs. Na/Na$^+$. While Na$_x$Cr$^{II}$Mn$^{III}$(PO$_4$)$_3$ exhibits a high theoretical energy density (566 W h kg$^{-1}$) for a gravimetric capacity of 160 mA h g$^{-1}$, only 10-20 mA h g$^{-1}$ was reported at voltages below 1.6 V vs. Na/Na$^+$. However, there remains a wide chemical space yet to be explored, which could yield new combinations of TMs enabling improved NaSICON electrode materials. A systematic study, either experimental or theoretical, of trends in voltages and the phase behavior of possible transition-metal combinations within NaSICON electrode materials has not yet been reported.

We present a first-principles study that charts the chemical space of 28 different Na$_x$M$_2$(PO$_4$)$_3$-electrode chemistries, where M and M’ can be any of the 3d TM, Ti, V, Cr, Mn, Fe, Co and Ni, with the Na content varying in the range of 1 ≤ x ≤ 4. We derive the intercalation voltages for all the 28 Na$_x$M$_2$(PO$_4$)$_3$ systems, validate our predictions with available experimental data, and identify promising NaSICON compositions to be targeted experimentally. We find new promising or not fully explored Na$_x$M$_2$(PO$_4$)$_3$ compositions, e.g., Na$_x$Mn$_2$(PO$_4$)$_3$ (1 ≤ x ≤ 4), Na$_x$Co$_2$(PO$_4$)$_3$ (3 ≤ x ≤ 4), Na$_x$TiCo(PO$_4$)$_3$ (2 ≤ x ≤ 4), Na$_x$VCo(PO$_4$)$_3$ (1 ≤ x ≤ 4), Na$_x$CrCo(PO$_4$)$_3$ (2 ≤ x ≤ 4), Na$_x$CoMn(PO$_4$)$_3$ (2 ≤ x ≤ 4) and Na$_x$CrFe(PO$_4$)$_3$ (2 ≤ x ≤ 4). We analyze the possible origins of the difficulties in synthesizing specific NaSICON chemistries.

2. Results

2.1 Structural features of Na$_x$M$_2$(PO$_4$)$_3$ electrodes

Depending on the TM species, temperature and/or Na content (x) per formula unit (f.u.) NaSICON materials typically adopt a rhombohedral (R3$\bar{c}$) or monoclinic (C2/c or Cc) or, in the specific case of $\alpha$-Na$_2$Ti$_{2}$Ti$_{IV}$(PO$_4$)$_3$,

2.2 Na intercalation in Na$_2$M$_2$(PO$_4$)$_3$, NaSICONs

The energetics of Na intercalation and the corresponding average voltages (see Methodology in Section 5) for single TM (M = M') NaSICON electrodes are shown in panels (a) and (b) of Fig. 2. The computed formation energies for the most stable orderings in Na$_2$M$_2$(PO$_4$)$_3$ are displayed in Fig. 2a as a function of Na concentration, where the lower energy envelopes form the so-called convex hull (solid lines) for a given Na$_2$M$_2$(PO$_4$)$_3$ system. The convex hull highlights the thermodynamic phase behavior at 0 K of Na (de)intercalation from/into the Na$_2$M$_2$(PO$_4$)$_3$ frameworks. Since the convex hull at 0 K does not include any entropic and pV effects, it informs on the propensity of Na to bond with the M$_2$(PO$_4$)$_3$ frameworks. Among the M = Ti, V, Cr, Mn, Fe, Co and Ni compounds, NaSICONs based on Ti, V, Cr and Fe have been reported experimentally.

From previous experimental work, the redox activities of Ti and V provide accessible Na concentrations ranging in 1 ≤ x ≤ 4, while Na$_{Cr}(PO_4)_3$ spans a narrower range of Na concentration (1 ≤ x ≤ 3), being limited by the Cr$^{IV}$/Cr$^{III}$ redox couple. Notably, the Cr$^{III}$/Cr$^{II}$ redox couple has not been cycled reversibly in NaSICON frameworks so far.

The structures represented by specific Na/vacancy orderings falling above the convex hull are thermodynamically unstable/metastable and are shown in Fig. S1–S7 of the ESL.

Note that the unstable Na/vacancy orderings should decompose to the closest ground state(s) identified by the convex hulls in Fig. 2a. For example, in Fig. S2, Na$_2$V$_2$(PO$_4$)$_3$ (C2) is found to be slightly metastable (~1.8 meV per atom above the stability line) and will phase separate into Na$_2$V$^{IV}$V$^{III}$(PO$_4$)$_3$ and Na$_2$V$^{VII}$(PO$_4$)$_3$. Given the small metastability of Na$_2$V$_2$(PO$_4$)$_3$, we expect this compound to be stabilized by entropic effects. Consequently, the stable structures lying on the convex hull (e.g., Na$_2$V$^{IV}$V$^{III}$(PO$_4$)$_3$) give rise to a “step” in the calculated Na voltage curve (see Fig. S2†). The convexity, that is the depth of the convex hull, is an indication of the thermodynamic stability of the specific Na/vacancy configurations. The calculated ground states on the convex hull do not necessarily correspond to topotactic structures since we allow changes to the symmetry (e.g., rhombohedral → monoclinic) of the host during deintercalation of Na from Na$_2$M$_2$(PO$_4$)$_3$ in our calculations.

Analyzing Fig. 2a and b, the following general trends can be deduced:

(i) The end member compositions in Na$_2$M$_2$(PO$_4$)$_3$, i.e., x = 1 and 4, typically adopt the rhombohedral (R$3c$ or R$3$) space group. Exceptions to this trend are Na$_2$Cr$^{III}$Ti$^{III}$(PO$_4$)$_3$ and Na$_2$Mn$^{III}$Mn$^{III}$(PO$_4$)$_3$, which are predicted to have triclinic (P1) symmetry probably due to Jahn–Teller distortions of high-spin...
Cr$^{2+}$ and Mn$^{3+}$ d$^4$ ions. These have not yet been observed experimentally.

(ii) A global minimum in the formation energy curves is present across all transition-metal Na$_3$M$_2$(PO$_4$)$_3$ systems at $x = 3$ (Fig. 2a).$^{41}$

(iii) Among all the Na$_3$M$^{3+}$M$^{3+}$(PO$_4$)$_3$ compounds investigated, Na$_3$Cr$^{3+}$Cr$^{3+}$(PO$_4$)$_3$ displays the deepest or lowest (i.e., most favorable) formation energy, followed by Na$_3$Fe$^{3+}$Fe$^{3+}$(PO$_4$)$_3$ > Na$_3$Ti$^{3+}$Ti$^{3+}$(PO$_4$)$_3$. This reflects the stability of the M$^{3+}$ oxidation states of these TMs. The stability of Na$_3$Cr$^{3+}$Cr$^{3+}$(PO$_4$)$_3$ is enhanced by the large ligand field stabilization energy of the Cr$^{3+}$ (3d$^3$) cation. The other compounds, Na$_3$Co$^{3+}$Co$^{3+}$(PO$_4$)$_3$, Na$_3$Cr$^{3+}$Cr$^{3+}$(PO$_4$)$_3$, and Na$_3$Ni$^{3+}$Ni$^{3+}$(PO$_4$)$_3$, display shallower (i.e., less favorable) formation energies (~25 meV per atom, Fig. 2a). The shallow convex hulls for Na$_3$Mn$_2$(PO$_4$)$_3$ and Na$_3$Ni$_2$(PO$_4$)$_3$ are caused by the Mn$^{3+}$ and Ni$^{3+}$ ions which are both Jahn–Teller active. The magnetic moment of Co$^{3+}$ Na$_3$Co$^{3+}$Co$^{3+}$(PO$_4$)$_3$ is ~3.0 $\mu_B$, indicating an intermediate spin state and possible Jahn–Teller activity.

(iv) Unsurprisingly, the deep minima in the convex hull plot of Fig. 2a lead to a large voltage step as shown in Fig. 2b and d, following the sequence Cr > Fe > Ti > V > Co > Mn > Ni.

(v) The M(III/II) redox couples that correspond to Na contents from $x = 3$ to $x = 4$, follow the voltage trend Ni > Co > Mn > Fe > Cr > V > Ti, while the M(IV/III) couples ($x = 1$ to $x = 3$) follow the sequence Ni > Co > Fe > Cr > Mn > V > Ti. Thus, Ni and Co (V and Ti) display the highest (lowest) average voltages for both M redox couples.

To validate our methodology, we have benchmarked our results against experimental observations in Na$_3$V$_2$(PO$_4$)$_3$, which has been extensively studied.$^{36,57,60}$ Experimentally, Na$_3$V$^{IV}$V$^{III}$(PO$_4$)$_3$ adopts monoclinic symmetry (C2/c) at room temperature, which is in qualitative agreement with our DFT calculations identifying the monoclinic ordering (Cc) as the stable structure at $x = 3$. From Fig. 2a, Na$_3$V$^{IV}$V$^{III}$(PO$_4$)$_3$ is on the convex hull with Na$_3$V$^{IV}$V$^{IV}$(PO$_4$)$_3$ and Na$_3$V$^{IV}$V$^{III}$(PO$_4$)$_3$, which adopt the rhombohedral space groups R3c and R3, respectively; this is consistent with X-ray diffraction experiments.$^{36,57,61}$ In Fig. 2b, the extraction of 2 Na atoms from Na$_3$V$^{IV}$V$^{III}$(PO$_4$)$_3$ gives rise to an average voltage of ~2.96 V vs. Na/Na$^+$ and corresponds to the V$^{IV}$/V$^{III}$ redox couple, while the insertion of Na into Na$_3$V$^{IV}$V$^{III}$(PO$_4$)$_3$ results in a voltage of 1.54 V (associated with the V$^{IV}$/V$^{III}$ redox couple). Experimentally, both the V redox couples (V$^{IV}$/V$^{III}$ and V$^{III}$/V$^{II}$) are involved in two-phase reaction mechanisms, yielding average voltages of ~3.40 V and ~1.63 V vs. Na/Na$^+$, respectively,$^{41}$ which are in reasonable agreement with our computed values. Notably, both GGA+U and hybrid functionals underestimate the computed voltages of Na$_3$V$_2$(PO$_4$)$_3$ (see Section S2 in the ESI†). Another important assessment to verify the validity of our simulations is ensuring that changes in oxidation states of the TMs upon Na extraction/insertion are captured. We verify that the correct redox processes do occur in our calculations by tracking the on-site magnetic moments on the TM atoms (Table S1†), as well as the transition metal coordination environments (Table S2†), which are discussed in Section S3 of the ESI†.

Whenever we could not assign the expected oxidation state of the TMs directly from the computed magnetic moments (e.g., in the cases of Fe, Co and Ni based NaSICONs), we inspected the density of states (DOS). Additional DOSs is are reported in Section S4 of the ESI (Fig. S9–S12).† As an example, we show in Fig. 3 the total and atom-projected DOS in Na$_3$V$_2$(PO$_4$)$_3$, for $x = 1,3$ and 4, which are the ground states identified in Fig. 2. The DOS is displayed for spin up and spin down states in the range of interest (~2.5 to 2 eV) around the Fermi energy. Unless a given structure is metallic, the top of the Fermi energy is arbitrarily set to the top of the valence band.

Panels (a) and (b) in Fig. 3 show the results for Na$_3$V$^{IV}$V$^{IV}$(PO$_4$)$_3$ and Na$_3$V$^{IV}$V$^{III}$(PO$_4$)$_3$, respectively. From the projected DOSs, the valence bands near the Fermi energy are occupied by 3d electrons of vanadium (red line), while the 2p O states (orange line) lie at lower energies. In general, the vanadium 3d states tend to dominate the valence band and shift at higher energies as more Na is inserted, closing the band gap (~1 eV for both compounds). The monoclinic distortion of
Na$_{3}$V$^{IV}$V$^{III}$(PO$_4$)$_3$ is responsible for an increase in the band gap ($\sim$1.8 eV) contrary to the Na$_x$Ti$_2$(PO$_4$)$_3$ trends. As expected, the intercalation of more Na$^+$ ions as in Na$_4$V$^{IV}$V$^{III}$(PO$_4$)$_3$ (Fig. 3c) further increases (destabilizes) the valence band, with this composition becoming gapless and showing a Fermi energy dominated by V(3d) states when GGA+$U$ is used. For the Na$_x$V$^{IV}$V$^{III}$(PO$_4$)$_3$, the band gap opens to $\sim$0.3 eV when the more accurate HSE06 hybrid functional is used at the relaxed HSE06 structure. Very recent hybrid functional simulations on Na$_x$Ti$_2$(PO$_4$)$_3$ have verified these orders of magnitude, with Na$_4$Ti$^{III}$Ti$^{III}$(PO$_4$)$_3$ showing a small band gap of $\sim$0.59 eV.$^{62}$

In the case of Na$_2$Ni$_2$(PO$_4$)$_3$, the projected DOS of Fig. S12† suggests metallic behavior at all the Na concentrations explored (i.e., $x = 1, 3$ and 4). Na$_x$Mn$_2$(PO$_4$)$_3$ and Na$_x$Co$_2$(PO$_4$)$_3$ show band gaps $>1.0$ eV at $x = 3$ and 4, but become metallic at $x = 1$, as shown in Fig. S9 and S11.† Na$_x$Fe$^{III}$Fe$^{IV}$(PO$_4$)$_3$ also appears, surprisingly, metallic (Fig. S10†), which introduces difficulties in localizing the Fe$^{III}$/Fe$^{IV}$ redox couple. Therefore, due to the apparent metallic behavior of some of these systems (Fe, Co and Ni-based NaSICONs), we were unable to assign unique oxidation states to their TMs. Notably, DFT is a ground state theory and not adequate in the prediction of accurate band gaps.$^{63}$

2.3 Na$^+$ ion intercalation in Na$_x$MM$^{'}$(PO$_4$)$_3$, NaSICON structures

We extend our analysis to the reversible extraction of Na from mixed Na$_x$MM$^{'}$(PO$_4$)$_3$ compounds where, for the sake of simplicity, the ratio $M : M^{'}$ is fixed as 1 : 1. While all the $M : M^{'}$ combinations have been considered, to simplify our discussion we concentrate on the cases where $M = Ti$, while $M^{'} = Ti, V, Cr, Mn, Fe, Co and Ni. Other mixed Na$_x$MM$^{'}$(PO$_4$)$_3$ are reported in

---

**Fig. 3** The total (gray) and atom projected (V red, O orange and Na yellow) DOS of the Na$_x$V$_2$(PO$_4$)$_3$ NaSICON (NVP), where for Na concentrations $x = 1$ (panel a), 3 (panel b) and 4 (panel c). The vertical line denotes the Fermi energy level and $E_g$ is the calculated band gap at the GGA+$U$ level of theory.

---

**Fig. 4** Panels (a) and (b) show the computed convex hulls as a function of Na concentrations ($x$) for Na$_x$TiM$^{'}$(PO$_4$)$_3$, where M$^{'} = Ti, V, Cr, Mn, Fe$ in panel (a) and M$^{'} = Co and Ni$ in panel (b). Panels (c) and (d) show the corresponding Na (de-)intercalation voltages over changes in the Na-content. The energies of unstable configurations for each convex hull, as well as complete voltage curves for each compound, are given in the ESI (Fig. S13–S33).† The symbols in panels (a) and (b) indicate stable ordered phases. To facilitate the visualization of the voltage curves near $\sim$2.8 V vs. Na/Na$^+$ the Ti–Cr curve in panel (c) has been slightly lifted, but it is expected to overlap the Ti–V and Ti–Mn voltage curves.
Section S5 of the ESI (Fig. S13–S33). The main reason behind choosing Ti-based mixed TM NaSICONs is their maximum experimental electrochemical data availability as compared to other combinations. Fig. 4a and b show the calculated convex hulls for experimentally reported and theoretical Na₃Ti³⁺(PO₄)₃ compounds, with Na contents in the range 1 ≤ x ≤ 4. Fig. 4c displays the corresponding voltages. Na₂Ti₂(PO₄)₃ is also reported in Fig. 4a and c as a reference.

Among the Na₃Ti³⁺(PO₄)₃ systems, only Na₃Ti₂(PO₄)₃, Na₆TiV(PO₄)₃, and Na₃TiMn(PO₄)₃ have been experimentally investigated over the entire Na composition range (1 ≤ x ≤ 4) while Na₃TiCr(PO₄)₃ (ref. 52 and 64) and Na₃TiFe(PO₄)₃ (ref. 52) have been studied in limited ranges of 1 ≤ x ≤ 3 and 2 ≤ x ≤ 4, respectively. Na₃TiCo(PO₄)₃ and Na₃TiNi(PO₄)₃ are theoretical compounds and have not yet been reported experimentally.

In general, the end member compositions at x = 1 and 4 (Fig. 4a and b) of the Ti–M NaSICON electrodes adopt rhombohedral symmetry (R3c or R3, or R32) except for Na₃Ti³⁺Cr³⁺(PO₄)₃ (PI) and Na₃Ti⁵⁺Fe⁵⁺(PO₄)₃ (P1), which are theoretically derived. This could be due to Jahn–Teller effects caused by the high-spin d⁴ electronic configurations of Cr³⁺ and Fe⁴⁺, respectively, as well as the low stability of Fe⁴⁺. For Na₆TiV(PO₄)₃ with M' = V, Mn, Co and Ni, a global minimum in the convex hull is located at x = 3, and the magnitudes of the formation energy follow the trend Ni > Co > Mn > V. On the other hand, the global minima for the M' = Ti, Cr and Fe NaSICONs are located at x = 2 (Fig. 4a), which is driven by the high stability of their stable oxidation states Ti⁴⁺, Cr³⁺ and Fe³⁺, respectively. Overall, the depth of the convex hulls (i.e., maximum magnitude of formation energies) for mixed TM NaSICONs follows the trend Fe > Cr > Ni > Co > Ti > Mn > V.

Fig. 4c and d present the computed voltages for Na extraction from Na₃Ti³⁺(PO₄)₃ in the composition range 1 ≤ x ≤ 4. Expectedly, the compound exhibiting the lowest intercalation voltage (~0.96 V) is Na₃Ti₂(PO₄)₃ for 3 ≤ x ≤ 4, which overestimates the experimental voltage (~0.4 V) reported by Senguttuvan et al. The DFT data of Fig. 4a suggest that an unreported stable phase appears at Na₃,TiFe(PO₄)₃, but with an oxidation state for Fe of 3.5 (Fe⁴⁺ + Fe⁵⁺). Although the highest Na intercalation voltage (~4.99 V) is computed for Na₆TiFe(PO₄)₃ between x = 1.5 and x = 1, the oxidation state of Fe would have to be +4, which may not be experimentally accessible in a reversible manner. We find that Na₃Fe⁴⁺Fe⁵⁺(PO₄)₃, where iron is expected to be Fe⁴⁺ appears metallic from the DOS in Fig. S10.

To assess the quality of our computed data, we analyzed in detail the experimentally reported data for Na₆Tiv(PO₄)₃. At x = 1, 2 and 4, Na₆Tiv(PO₄)₃ has rhombohedral symmetry (R3c), while the structure of Na₆TiFe(PO₄)₃ is monoclinic (C2/c). Our calculations reproduce the rhombohedral symmetry (R3c) at x = 1 and 4 and the monoclinic symmetry (Cc) at x = 3, whereas we find a triclinic structure (P1) for Na₃Tiv(PO₄)₃. The Na₆Tiv(PO₄)₃ convex hull (Fig. 4a) displays a minimum at x = 3, analogous to the observed minima in the Na₆Mₓ(PO₄)₃ systems (Fig. 2a); this also provides the largest step in the corresponding voltage profile of Fig. 4c. In particular, the Na extraction from Na₆Ti⁵⁺V³⁺(PO₄)₃ takes place through the redox couples V⁵⁺/V⁴⁺ 1.54 V (experimentally ~1.6 V ⁴⁸,⁴⁹), Ti⁴⁺/Ti³⁺ 2.50 V (~2.1 V), and V⁴⁺/V³⁺ 2.90 V (~3.4 V) vs. Na/Na⁺, respectively. The mechanism of Na extraction from Na₆Ti⁵⁺V³⁺(PO₄)₃ has been shown to occur via a solid-solution mechanism for the V⁴⁺/V³⁺ redox couple, followed by a two-phase reaction for both the Ti⁴⁺/Ti³⁺ and V⁴⁺/V³⁺ redox couples.⁴⁸

Due to the existence of multiple voltage steps in Na₆MₓM'M'(PO₄)₃ (where M' = Ti, V, Cr, Mn, Fe, Co and Ni and M = Ti), we directly compare the computed average voltage per Na⁺ exchanged over the entire composition range (i.e., 1 ≤ x ≤ 4), as shown in Fig. 5. Importantly, the overall average voltage monotonically increases from Ti to Ni in cases where M = M' and M = Ti, which is consistent with trends in standard reduction potentials of the transition metals. We note that the M'⁴⁺ ions, in particular, become more oxidizing as one crosses the transition series from Ti to Ni, with the lack of voltage increase from Mn to Fe reflecting the stability of their 3d⁹ configurations. Specifically, the calculated voltages increase from ~1.96 V (for Ti) to ~4.40 V vs. Na/Na⁺ (for Ni) in Na₆Mₓ(PO₄)₃ (green line in Fig. 5), while the maximum voltage is ~3.73 V for Ti–Ni in the case of Na₆MₓM'(PO₄)₃ (M = Ti) systems (orange line). Notably, the voltage values for Na₆Tiv(PO₄)₃ are consistently lower than those for the corresponding Na₆Mₓ(PO₄)₃, indicating that replacing Ti with another 3d metal will always lead to an increased average voltage in both M = M' and Ti–M' systems.

2.4 Intercalation voltages of Na₆M₃M'(PO₄)₃

Fig. 6 consolidates the computed voltages of 28 plausible combinations of 3d TMs in Na₆M₃M'(PO₄)₃ with M and M' in a 1 : 1 ratio. In Fig. 6, the boxes outlined in red represent the
average voltage per extracted Na in the entire $1 \leq x \leq 4$ concentration range for each combination of TM. The NaSICON systems investigated cover a range of average voltages from $1.96$ to $4.4$ V vs. Na/Na$^+$. Redox couples are indicated in each box whenever we could identify the appropriate oxidation states as described in Section 2.2. The diagonal of Fig. 6 displays the single-TM NaSICONS ($M = M'$), whose average voltages map directly to Fig. 5. Notably, the highest average voltages of $4.3$ to $4.4$ V are attained by the theoretical Na$_x$Ni$_2$(PO$_4$)$_3$, Na$_x$CoNi(PO$_4$)$_3$ and Na$_x$FeNi(PO$_4$)$_3$ compounds. In general, voltages in NaSICONs are set by the redox couples $M^{III}/M^{II}$ and $M^{IV}/M^{III}$ but notable exceptions to this trend are for V and Nb-based

![Fig. 6](image)

**Fig. 6** A voltage map derived from our calculations of 3d NaSICON electrodes, Na$_x$M$^0$(PO$_4$)$_3$, where M and M$^0$ = Ti, V, Cr, Mn, Fe, Co and Ni. The text in each box represents the redox pair and the corresponding voltage vs. Na/Na$^+$ (given by the color bar). The color of the text in the sub-boxes (black or white) does not have any physical significance other than to enhance the visibility of the plot. The color fill in each sub-box represents the voltage from the scale given on the right. The red-outlined bottom sub-box reflects the average voltage per Na in the overall range of $1 \leq x \leq 4$.

![Fig. 7](image)

**Fig. 7** Panels (a) and (b) show portions of the computed phase diagrams of Na–P–O–Mn and Na–P–O–Co at 0 K. Two stable NaSICON structures, i.e., Na$_2$Mn$_2$(PO$_4$)$_3$ and Na$_2$Co$_2$(PO$_4$)$_3$, are observed in the phase diagram of Na–P–O–Mn, which are in equilibrium with the highly stable binary (P$_2$O$_5$ and Mn$_2$O$_3$) and ternary (NaMn$_2$O$_3$ and NaP$_2$O$_5$) compounds. In panel (b), a stable NaSICON structure, i.e., Na$_2$Co$_2$(PO$_4$)$_3$, is observed in the phase diagram of Na–P–O–Co, which is in equilibrium with the highly stable binary (P$_2$O$_5$ and Co$_3$O$_4$) and ternary (NaCo$_2$O$_3$ and NaP$_2$O$_5$) compounds.
2.5 Thermodynamic stabilities of selected Na$_2$M$_2$(PO$_4$)$_3$ compounds

The calculated quaternary phase diagrams for the systems Na–P–O–Mn, Na–P–O–Co, and Na–P–O–Ni (Fig. 7 and S34 in the ESIF) reflect the stabilities of the unreported NaSICONs with these transition metals compared with the stable elemental, binary, ternary and quaternary phases. While it remains extremely challenging to characterize quaternary (and beyond) phase diagrams solely based on sparse experimental data, theory provides a viable alternative for investigating such complex systems. We calculated all the binary/ternary/quaternary compounds available in the inorganic crystal structure database (ICSD) within the Na–P–O–Mn, –Co and –Ni quaternary systems.

Table 1 Experimentally observed Na$_x$MM'$(PO_4)_3$ phases along with the corresponding Na concentrations, structures, Na$^+$ reversible intercalation voltages, redox couples, mechanism of Na$^+$ intercalation, and gravimetric capacities. The intercalation voltages (in V) and theoretical (Theo.) capacities (in mA h g$^{-1}$) are shown. Rev. and Irrev. indicate experimentally reversible and irreversible processes. ? is used whenever the space group of a specific phase is unknown or not reported. Intercalation voltages account for the number of Na$^+$ ions exchanged. Whenever available, the space group of each phase is reported. For a transparent comparison between theoretical and experimentally reported capacities, the reported capacities are renormalized to the molecular weight of Na$_x$MM'$(PO_4)_3$.

Fig. 7a shows the computed phase diagram of the Na–P–O–Mn system, where open circles correspond to stable phases in the global phase diagrams and the black lines show the equilibria among various compounds. The computed phase diagram of Na–Mn–P–O shows that Na$_2$Mn$^{III}$Mn$^{III}$(PO$_4$)$_3$ and Na$_2$Mn$^{IV}$Mn$^{IV}$(PO$_4$)$_3$ are stable compounds. Na$_2$Mn$^{III}$Mn$^{III}$(PO$_4$)$_3$ has the structure of the monoclinic (Cc) polymorph, whereas Na$_2$Mn$^{IV}$Mn$^{IV}$(PO$_4$)$_3$ has a rhombohedral (R$3$) structure. From our computations, we observed a Jahn–Teller distortion driven by the Mn$^{IV}$ 3d$^4$ ion and highlighted by four longer equatorial bonds of ~2.10 Å and two shorter axial bonds of ~1.96 Å. No Ni-containing NaSICON phases appear stable in the Na–Ni–P–O system (Fig. S34). In the Na–Co–P–O phase diagram (Fig. 7b), only Na$_2$Co$^{III}$Co$^{III}$(PO$_4$)$_3$ appears stable and exhibits rhombohedral symmetry (R$3$). From this analysis, it is predicted that Na$_2$Mn$^{III}$Mn$^{III}$(PO$_4$)$_3$, Na$_2$Mn$^{IV}$Mn$^{IV}$(PO$_4$)$_3$, and Na$_2$Co$^{III}$Co$^{III}$(PO$_4$)$_3$ have the potential for successful experimental synthesis, given their thermodynamic stabilities.
3. Discussion

Using first-principles calculations, we investigated the electrochemical properties of 28 transition-metal-based NaSICONs as cathode materials for NIBs. To guide our discussion, we summarize the reported experimental voltages and the experimental gravimetric and the theoretical gravimetric capacities of some Na$_{x}$M$_{2}$(PO$_4$)$_3$ systems in Table 1. For a transparent and fair comparison between the theoretical and experimentally reported capacities in Table 1, the reported capacities are renormalized from the reported composition (pristine) to the molecular weight of the Na$_{x}$M$_{2}$(PO$_4$)$_3$. The theoretical capacities are also computed with respect to the Na$_{x}$M$_{2}$(PO$_4$)$_3$ compounds.

Among the Na$_{x}$M$_{2}$(PO$_4$)$_3$ compounds, Na$_{x}$Cr$_2$(PO$_4$)$_3$ delivers the highest measured voltage of ~4.5 V (~4 V calculated theoretically) vs. Na/Na$^+$, albeit with a limited capacity of just ~98 mA h g$^{-1}$ and corresponding to the extraction of 2 Na from Na$_{2}$CrVI$^{3+}$(PO$_4$)$_3$ to form Na$_{2}$Cr$^{4+}$Cr$^{3+}$(PO$_4$)$_3$. Na$_{x}$Cr$_2$(PO$_4$)$_3$ has not yet been obtained by either a chemical or an electrochemical process. Na$_{x}$CrVI$^{3+}$(PO$_4$)$_3$ would require Cr to exist in a mixed, Cr$^{3+}$/Cr$^{6+}$ oxidation state, with Cr$^{3+}$ (high-spin d$^3$) typically being an unstable oxidation state for Cr and easily prone to Jahn–Teller distortions in octahedral environments, e.g., NaSICON.$^{6,7}$

Na$_{x}$V$_2$(PO$_4$)$_3$ exhibits the 2nd highest measured voltage of the single TM NaSICONs, with a computed average voltage of ~2.48 V vs. Na/Na$^+$ (Fig. 5). With the same number of maximum electrons exchanged in Na$_{x}$M$_{2}$(PO$_4$)$_3$ (where M = Ti or V), and Ti being lighter than V, Na$_{x}$Ti$_2$(PO$_4$)$_3$ is expected to show the largest gravimetric capacity. Na$_{x}$Ti$_2$(PO$_4$)$_3$ and NVP provide the largest reported theoretical gravimetric capacities (~170.1 mA h g$^{-1}$ and ~167.9 mA h g$^{-1}$ for Na$_{x}$M$_{2}$(PO$_4$)$_3$) in single TM NaSICONs. In theory, additional capacity and an increased voltage could be achieved by exploiting the V$^4+/V^3+$ redox couple in the reaction Na$_{x}$V$^4+$/V$^3+$(PO$_4$)$_3$ $\rightarrow$ Na$^+ + 1$e$^- + V^{4+}V^{3+}$(PO$_4$)$_3$. While the seminal report by Gopalakrishnan et al. suggested the possibility of chemically extracting the last Na$^+$ ion to form V$^4+$/V$^3+$ (PO$_4$)$_3$, subsequent attempts to do so have proven unsuccessful. Note that V$^4+$/V$^3+$ (PO$_4$)$_3$ is not a thermodynamically stable compound$^{43}$ and is predicted to decompose into VPO$_5$ + V$_2$P$_2$O$_7$.

We assessed the existence of uncharted single-TM NaSICONs, which are Ni, Co and Mn. Except for Na$_{x}$Mn$^4+$Mn$^4+$(PO$_4$)$_3$, Na$_{x}$Mn$^{3+}$Mn$^{3+}$(PO$_4$)$_3$ and Na$_{x}$Co$^{3+}$Co$^{3+}$(PO$_4$)$_3$, that appear stable according to our convex hulls but have not been reported experimentally, our analysis of the phase diagrams indicates that Ni- and Co-NaSICONs are generally unstable. However, Mn has been mixed effectively with Ti, V and Cr, while Ni-V mixed NaSICONs have also been made (Table 1).$^{48}$ In particular, Zhou et al. and later Chen and collaborators$^{44}$ synthesized Mn$^{3+}$-containing Na$_{x}$Mn$^{4+}$V$^3+$(PO$_4$)$_3$, which upon Na extraction exploits the Mn$^{4+}$/Mn$^{3+}$ redox couple and Mn$^{3+}$ 3d$^3$ is Jahn–Teller active.

In the case of mixed Na$_{x}$MM$^{3+}$(PO$_4$)$_3$, NaSICONs, we kept the M : M$^+$ ratio to 1 : 1. From an extensive assessment of polyanion electrodes, Masquelier and Croguennec$^{47}$ observed that the redox potentials of specific TMs remain nearly independent of other TMs that may be present. This general rule is also well supported by the simulations that are summarized in Fig. 6. Based on this general principle, one can envision selected combinations of TMs delivering reversible high voltages vs. Na/Na$^+$. For example, the Ti$^{IV}$/Ti$^{III}$ redox couple showed a similar voltage$^{7}$ (~2.1 V vs. Na/Na$^+$) in three related NaSICON systems: Na$_{2}$Ti$_2$(PO$_4$)$_3$, Na$_{2}$TiNb(PO$_4$)$_3$ and Na$_{2}$TiFe(PO$_4$)$_3$. Notably, in experiments, there is a consistent shift of ~0.3 V between the voltages measured vs. Na/Na$^+$ compared to those measured vs. Li/Li$^+$. The Na$_2$Ti$^V$(PO$_4$)$_3$ system has been provided to show the largest gravimetric capacity (~187.1 mA h g$^{-1}$, Table 1) among NaSICONs as a result of the accessibility of several V$^V$/V$^IV$ and Ti$^IV$/Ti$^III$ redox couples. Nevertheless, the computed average voltage (~2.3 V, Fig. 6) of Na$_2$Ti$^V$(PO$_4$)$_3$ highlights the low energy density of the system.$^{48,49}$ More promising in terms of overall capacities and voltages, and thus energy density, are Na$_4$TiCr(PO$_4$)$_3$, Na$_x$TiMn(PO$_4$)$_3$, Na$_3$x$^IV$Cr$_x$(PO$_4$)$_3$, Na$_x$V$_x$Cr(PO$_4$)$_3$, and Na$_x$V$_x$Mn(PO$_4$)$_3$. However, the reversible extraction/insertion of Na from some of these systems remains to be verified. Excluding some specific exceptions, especially Fe, Co and Ni based NaSICONs since they appear metallic, our simulations are also able to capture the mechanism of Na intercalation in mixed NaSICON electrodes. For example, Na$_{3}$VFe(PO$_4$)$_3$ has been reported to reversibly insert Na with the activation of the Fe$^{III}$/Fe$^{II}$ and V$^{IV}$/V$^{III}$ redox couples (see Table 1), and this behavior is reproduced by our calculations (Fig. 6 and S21 of the ES†). Similar conclusions can be advanced for mixed TiV, TiCr, VCr and CrMn NaSICON materials.

From our analysis (Fig. 6), specific unexplored combinations of TMs appear to be worthy of future study. Our calculations suggest promising NaSICON compositions in terms of average voltages, such as TiCo, VCo, CrFe and CrCo NaSICONs as reported in Fig. 5 and Table 1. Both CrFe and CrCo NaSICONs are predicted to exploit the high voltage Cr$^V$/Cr$^III$ redox couple, which has been proven effective in other mixed NaSICONs, e.g., TiCr, VCr and MnCr.$^{47,48}$ Although the addition of Co into Ti, V and Cr appears interesting, our analysis of the Na$_4$Co$_2$(PO$_4$)$_3$ system suggests that only Na$_4$Co$^{3+}$Co$^{3+}$(PO$_4$)$_3$ with Co$^{3+}$ 3d$^3$ (low spin) is thermodynamically stable, but this compound has not yet been synthesized. While one would target compounds with Co$^{3+}$ to ensure high voltages, it appears possible to introduce Co in smaller proportions than 1 : 1 ratio, but more experimental and theoretical work is required.

We do not anticipate Ni to be of importance in mixed NaSICON systems due to the high instability of quaternary Na$_{x}$Ni$_{2}$(PO$_4$)$_3$. Manoun et al.$^{72}$ briefly reported the synthesis of Na$_{x}$Cr$^{3+}$Ni$^{3+}$(PO$_4$)$_3$. A recent report by Zhou et al.$^{35}$ claimed the extraction of Na from Na$_x$VNi(PO$_4$)$_3$ (Table 1) involving the redox couples V$^IV$/V$^III$, V$^V$/V$^IV$, and Ni$^{II}$/Ni$^{III}$. Nevertheless, we speculate that the Ni content of the materials is not in a 1 : 1 ratio but appears to be significantly lower. Furthermore, the highest voltage accessed (~4.3 V vs. Na/Na$^+$) during the electrochemical cycling is lower than that of the expected Ni redox couple. While our DFT calculations seem to verify the activity of the V$^IV$/V$^III$ and V$^V$/V$^IV$ redox couples in Na$_x$VNi(PO$_4$)$_3$ (Fig. 6), we are unable to verify the oxidation states involved in the
Ni^{III}/Ni^{IV} reaction from the computed magnetic moments as the material becomes metallic in our simulations (Fig. S12). Our findings also cast doubt on the activity of Ni in this compound as reflected by the limited gravimetric capacity reported experimentally (∼80 mAh g⁻¹).²

4. Conclusions

Using ab initio density functional theory and thermodynamics, we explored the full chemical map of 3d TM-based NaSICON phosphate Na₄MM′(PO₄)₃ (M, M′ = Ti, V, Cr, Mn, Fe and Ni) cathode materials for high-energy density and safe sodium-ion batteries. We identified the ground state structures at various Na contents as well as the corresponding Na-intercalation voltages and redox processes for 28 distinct NaSICON compositions of which only 13 have been reported experimentally.

Further, we investigated the Na-intercalation properties of previously unreported Na₂Mn(PO₄)₃ and Na₂VCo(PO₄)₃ (1 ≤ x ≤ 4), among others. The calculated quaternary phase diagrams of the Na–P–O–M (M = Mn, Co and Ni) chemical systems indicate the instability of Ni and most Co-based NaSICONs, though the Na₂MnIVMnIV(PO₄)₃, Na₂MnIII-MnIII(PO₄)₃ and Na₂CoIIICoIII(PO₄)₃ compounds are identified as stable compositions. We performed a complete analysis of the wide-ranging chemical space of NaSICON phosphate cathode materials for Na-ion batteries, and our work can be used to guide further experimental synthesis of the new and promising compositions identified here. We plan to synthesize the promising electrode compositions identified in this work.

5. Methodology

We used the Vienna ab initio simulation package (VASP)³⁷,³⁸ for ab initio density functional theory (DFT) total energy calculations. The projector augmented wave (PAW) potentials were used for the core wave-functions. The Perdew–Burke–Ernzerhof (PBE) parameterized spin-polarized generalized gradient approximation (GGA) was used for the exchange and correlation energy.³⁷ The strong on-site coulomb correlation of 3d electrons of the TM (Ti, V, Cr, Mn, Fe, Co and Ni) is addressed with Hubbard’s U correction according to the Dudarev method.⁷⁷ The effective U parameters used were 4.0 eV for Ti,³⁸ 3.1 for V, 3.5 for Cr, 3.9 for Mn, 4.0 for Fe, 3.4 for Co, and 6.0 for Ni,³⁸ and they were fitted to match the experimental formation energies of binary oxides. We also introduced an empirical correction of 1.36 eV per O₂ (ref. 79) to remedy the spurious error originating from the well-known over-binding of O while using GGA.

The periodic wave functions were expanded in terms of plane waves up to a kinetic energy cut-off of 520 eV. The PAW potentials used to describe the core electrons of the following atomic species were: Na 08Apr2002 3s¹, P 17Jan2003 2s²3p³, O 08Apr2002 2s²2p⁴, Ti 08Apr2002 3d³4s¹, V_pv 07Sep2000 3p³4s⁴, Cr 06Sep2000 3d⁵4s¹, Mn 06Sep2000 3d⁵4s¹, Fe 06Sep2000 3d⁵4s¹, Co 06Sep2000 3d⁵4s¹, and Ni 06Sep2000 3d⁵4s¹. Additionally, a Γ-centered Monkhorst–Pack k-point mesh with 25 subdivisions along each reciprocal lattice vector was applied to all structures. Using these settings, the total energy of each structure was converged to within 10⁻⁵ eV per cell, atomic forces within 10⁻² eV per Å and the stress within 0.29 GPa.

An intercalation battery based on the NaSICON cathode electrodes implies the reversible insertion/extraction of Na⁺ ions into/from the Na₄MM′(PO₄)₃ framework according to the redox reaction of eqn (1).

\[
\begin{align*}
\text{Na}_4\text{MM}'(\text{PO}_4)_3 + (x - y)\text{Na}^+ + (x - y)e^- & \quad \xrightarrow{\Delta G^0} \quad \text{Na}_x\text{MM}'(\text{PO}_4)_3 \\
\end{align*}
\]

where y and x are the initial and final Na contents in the NaSICON framework and ΔG⁰ is the change of Gibbs energy at 0 K for the reaction of eqn (1). Here, we approximated the Gibbs energy of each component by the DFT total energies \(i.e., G = E\), thus neglecting the pV and entropic contributions. The average voltage across an intercalation extent \((x - y)\) can be calculated from the ΔG⁰, as in eqn (2).

\[
V = -\frac{\Delta G^0}{(x - y)F} = -\frac{\langle [\text{Na}_x\text{MM}'(\text{PO}_4)_3] - [\text{E}(\text{Na}_x\text{MM}'(\text{PO}_4)_3)] + (x - y)\mu_{\text{Na}} \rangle}{(x - y)F}
\]

where \(\mu_{\text{Na}}\) is the Na chemical potential (set to bulk Na metal) and \(F\) is the Faraday constant.

To establish the general phase behavior of Na (de)intercalation into the Na₄MM′(PO₄)₃ structure, we monitored, using eqn (3), the formation energies \(E_f(x)\) of various Na/vacancy orderings at different Na concentrations, \(x (1 ≤ x ≤ 4)\), with respect to the DFT energies of the fully discharged \(i.e., [\text{E}(\text{Na}_x\text{MM}'(\text{PO}_4)_3)]\) and fully charged \([\text{E}(\text{Na}_x\text{MM}'(\text{PO}_4)_3)]\) configurations.

\[
E_f(x) = E[\text{Na}_x\text{MM}'(\text{PO}_4)_3] - \left(\frac{4 - x}{3}\right)E[\text{Na}_4\text{MM}'(\text{PO}_4)_3]
\]

Different NaSICON structures were studied according to specific Na concentrations in Na₄MM′(PO₄)₃, with M and M′ = Ti, V, Cr, Mn, Fe, Co, and Ni. In choosing the amount of mixing of TM in these NaSICON structures, we have considered only two distinct situations: (i) \(M = M'\), which leads to Na₂Mₓ(PO₄)₃, and (ii) \(M = M'\) in the ratio \(1 : 1\).

When fully sodiated, the fully ordered rhombohedral symmetry (\(R\bar{3}c\)) of the high-temperature NaSICON structure is typically observed \(i.e., \text{Na}_4\text{Fe}^{III}\text{Fe}^{II}(\text{PO}_4)_3\) (ref. 59) and is therefore our starting model to study Na removal and TM mixing. Na vacancies are created in the fully sodiated structure Na₄MM′(PO₄)₃, resulting in NaₓMM′(PO₄)₃, where the Na content varies in the range of \(1 ≤ x ≤ 4\) in steps of \(\Delta x = 0.5\). The possible configurations originating from the various orderings of Na and vacancies \(V_a\) in the NaSICON are obtained using the pymatgen library.⁸¹ A ranking according to the classical Ewald energy on basis charges \(i.e., \text{Na} = +1, \text{P} = +5, \text{O} = -2\)
and the variable charge on the TM (+2, +3 and +4) is applied to limit the number of possible structures to a computationally tractable level. For mixed TM NaSICONs, the ordering of M and M’ is simultaneously performed with that of Na and Va. DFT calculations are performed on the primitive cell and supercells (2 x 1 x 1) of these orderings. A formula unit of the fully discharged NaSICON [Na2MM(PO4)3] contains 21 atoms.
